LOCK DELEGATION WITH SPACE-EFFICIENT LOCK MANAGEMENT

Laurent P. Daynès

RELATED APPLICATIONS

[1001] This application is related to co-pending U.S. Patent Application No. XX/xxx,xxx, <not yet assigned>, entitled, "Validation Technique for Bulk Lock Delegation," and naming Laurent P. Daynès, filed on even date herewith, the entirety of which is incorporated herein by reference.

BACKGROUND

Field of the Invention

[1002] The invention relates to concurrency control and, in particular, to lock management techniques that allow efficient bulk delegation of locks in database and/or transaction processing systems.

Description of the Related Art

[1003] Delegation of locks forms a basis for concurrency control in many modern transaction models, such as nested transaction models (*see e.g.*, J.E.B. Moss, *Nested Transactions: An Approach to Reliable Distributed Computing*, Ph.D. thesis, Massachusetts Institute of Technology, April 1981; T. Harder and K. Rothermel, *Concurrency Control Issues in Nested Transactions*, VLDB Journal, 2(1):39-74, 1993), split-join transaction models (*see e.g.*, C. Pu, G.E. Kaiser, and N. Hutchinson, *Split-Transactions for Open-Ended Activities*, In Proc. of the ACM SIGMOD Int. Conf. on Management of Data, pp. 26-37, 1988; G.E. Kaiser and C. Pu, *Dynamic Restructuring of Transactions*, In Database Transaction Models for Advanced Applications, Data Management Systems, Morgan-Kaufman, pp. 266-295, 1992), colored actions (*see e.g.*,

S.K. Shrivastava and S.M. Wheeler, *Implementing Fault-Tolerant Distributed Applications Using Objects and Multi-coloured Actions*, In Proc. of the Int. Conf. on Distributed Computing Systems, pp. 203-210, 1990), or the Apotram transaction model (see O. Anfindsen, *Apotram - an Application-Oriented Transaction Model*, Ph.D. thesis, University of Oslo, Department of Informatics, 1997). Various of these models are characterized by the delegation of locks at some point in the life of a transaction or assimilated entity. For example, the join operation of split-join transactions is a straightforward use of lock delegation. In the nested transaction model, a sub-transaction delegates all its locks to its parent transaction upon its commit. Similarly, lock delegation can be used to achieve the effect of moving objects upward or downward in a hierarchy of nested databases. Typically, a transaction model that imposes hierarchical structure and relies on locking for concurrency control uses some form of lock delegation to control lock ownership across levels of the hierarchy.

[1004] Often, transaction models assume that a transaction may delegate a single lock or a specific subset of its locks to other transactions. Often, it is desirable to delegate locks in bulk. For example, bulk delegation is assumed for most hierarchical transaction models, such as the nested transaction model, where delegation is useful to transfer the locks of a committed transaction to the next transaction up the hierarchy. Because commitment of a nested transaction is a common case, special attention should be paid to optimize bulk delegation. Unfortunately, most implementations focus on the case of single lock delegation and do not pay particular attention to efficiency of bulk delegation, instead implementing bulk delegation as a sequence of single lock delegation operations. Typically, such implementations of bulk delegation involve traversing and updating linked-lists of lock request control blocks (LRCBs). Scaling performance of such implementations is poor.

[1005] One alternative bulk delegation technique is the applicants own prior work (described in L. Daynes, M.P. Atkinson, and P. Valduriez, *Efficient Support for Customizing Concurrency Control in Persistent Java*, In E. Bertino, S. Jajodia, and L. Kerschberg, editors, International Workshop on Advanced Transaction Models and

Architectures (ATMA), pp. 216-233, Goa, India, September 1996). Using that technique, the effect of a bulk lock delegation is achieved not by updating individual locks, but by changing the conflict detection mechanisms of the delegatee, using a lock manager ability's to represent ignore-conflict relationships between transactions. Unfortunately, while that technique tends to decouple the cost of bulk delegation from the number of locks delegated, it still suffers from poor scaling performance because space used to represent locks grows in proportion with the number of locks represented.

[1006] What is needed are low-space overhead techniques that facilitate efficient bulk delegation, particularly in implementations that demand fine-granularity locking and in which transactions tend to acquire large numbers of locks.

SUMMARY

[1007] Accordingly, techniques have been developed whereby lock state sharing can be extended to provide a low-space overhead lock management facility with comprehensive support for bulk lock delegation. Operating in conjunction with delegation request validation methods, the techniques provide an efficient bulk lock delegation facility for many advanced transaction models. Some implementations in accordance with the present invention provide bulk lock delegation with computational costs that are generally independent of the number of locks being delegated. Accordingly, such implementations may be particularly attractive for systems that demand for fine-granularity locking, large transaction sizes (in term of number of locks acquired), and efficient delegation mechanisms. Embodiments in accordance with the claims that follow will be understood with reference to the description and drawings herein.

BRIEF DESCRIPTION OF THE DRAWINGS

[1008] The present invention may be better understood, and its numerous objects, features, and advantages made apparent to those skilled in the art by referencing the accompanying drawings.

[1009] **FIG. 1** depicts relationships between locked resources and locks represented using references to shared lock states during lock acquisition in accordance with some embodiments of the present invention.

[1010] **FIG. 2** is a flowchart that depicts an exemplary functional sequence for performing a bulk delegation of locks in accordance with some embodiments of the present invention.

[1011] **FIG. 3** depicts pseudocode that provides an exemplary functional sequence for performing a bulk delegation of locks in accordance with some embodiments of the present invention.

[1012] **FIG. 4** depicts pseudocode that provides an exemplary functional sequence for determining the validity of a delegation of a lock value from one or more delegators to one or more delegates in accordance with some embodiments of the present invention.

[1013] **FIG. 5** is a flowchart that depicts an exemplary functional sequence in accordance with some embodiments of the present invention, in which validity of a bulk delegation request is determined using an initial conservative, but computationally efficient, test or tests and, if such an initial test is inconclusive, using a thorough evaluation of the delegation request for each shared lock state to which it applies.

[1014] **FIG. 6** depicts pseudocode that provides an exemplary functional sequence in accordance with some embodiments of the present invention for determining the validity of a bulk delegation.

The use of the same reference symbols in different drawings indicates similar or identical items.

DESCRIPTION OF THE PREFERRED EMBODIMENT(S)

[1015] The description that follows presents a set of techniques, systems, objects, functional sequences and data structures associated with concurrency controls for cooperative operations on resources. An exemplary implementation focuses on an

environment in which the semantics of certain operations are provided, at least in part, using a bulk lock delegation mechanism and ignore conflict relationships between transactions. For example, in an exploitation for a transaction model that implements a nested conflict serializability correctness criterion, such as described in U.S. Patent Application No. 09/714,336, entitled "Implementation of Nested Databases using Flexible Locking Mechanisms" and naming Laurent Daynès and Ole Jørgen Anfinsen as inventors, bulk lock delegation may be used to support operations such as creation, commitment or abortion of a sub-database or sub-transaction using techniques of the present invention. To facilitate understanding of one such exploitation, U.S. Patent Application No. 09/714,336 is incorporated in its entirety herein by reference. Nonetheless, other exploitations for other transaction models, now defined or hereafter developed, may also employ techniques of the present invention for, or to facilitate, computationally efficient bulk delegation of locks.

[1016] In general, techniques, systems, objects, functional sequences and data structures of the present invention may be used in combination and/or integrated with applications, locking facilities and/or transaction processing systems. For example, without limitation, realizations in accordance with the present invention may be embodied as (1) functionality integrated or supplied with transaction generating applications (e.g., as functions, libraries or services thereof), as (2) functionality (e.g., as processes, services, etc.) interposed or suitable as an intermediary between transaction generating applications and a locking facility of a transaction processing system, (3) as functionality providing such a locking facility, or as (4) functionality supporting a bulk lock delegation in a database or transaction processing system that employs lock state sharing as part of its underlying lock management facility. Furthermore, while much of the description that follows focuses on transactions, persons of ordinary skill in the art will appreciate based on the description herein that systems are envisioned in which locks (or more generally, locking capabilities) are associated with a variety of entities (e.g., transactions, cooperating groups, logical databases, etc.) that control visibility of shared data or resources.

Terminology

Bulk Delegation

[1017] This patent application describes techniques to efficiently implement lock delegation, a locking operation that atomically transfers ownership of a lock. As will be described in detail below, one particular advantage of these techniques is their computational efficiency when employed to implement bulk lock delegations, e.g., delegation of all locks owned by a particular transaction to one or more delegatee transactions. In particular, some implementations of the techniques exhibit the desirable property that computational cost of a bulk delegation is independent of the number of locks delegated.

[1018] In general, lock delegation takes place between two transactions, the *delegator* and the *delegatee*. However, in some cases, more complex forms of bulk lock delegation may be desirable. For instance, multiple owners of a given lock may simultaneously delegate their locks to a single delegatee. Similarly, a single delegator may need to simultaneously delegate its lock(s) to more than one delegatee. In general, multiple delegators, multiple delegatees and/or multiple locks may be transferred as part of a bulk lock delegation. In some exploitations, all locks held by a set of delegators will be transferred as part of a bulk lock delegation to a set of delegatees; however in some implementations it may be desirable to delegate only locks owned (or held) in a particular mode: e.g., read locks, write locks, locks protecting new objects only, etc.

[1019] Therefore, for purposes of illustration, a generic bulk lock delegation operation will be understood to include three parameters:

1. a list of delegator(s),
2. a list of delegatee(s), and
3. some identification of the type of locks that are to be delegated.

However, based on the description herein, persons of ordinary skill in the art will appreciate other less-fully-parameterized operations that may be suitable for a particular

realization. For example, some realizations need not discriminate between lock types. In some realizations, one-to-many or many-to-one bulk delegation need not be implemented. Whatever the particular mix of bulk delegation requirements, persons of ordinary skill in the art will recognize suitable implementations based on the description herein.

Lock State Sharing

[1020] In general, the terms lock, lock value and lock state denote three different things: (1) a lock holds information about who can access in what mode the resource it is associated with, (2) a lock value is an encoding of the information held by a lock, and (3) a lock state is a data structure that holds a particular lock value.

[1021] Lock state sharing techniques are based on the observation that many locks end up having the same value. Hence, instead of representing each individual lock with a distinct data structure (i.e., a distinct lock state), a lock can be represented by a reference (e.g., a virtual memory pointer) to a single data structure that holds the value of that lock. In other words, multiple locks with the same value are implemented as multiple references to the same lock state holding that lock value (hence the name shared lock states, since the same lock state is used to represent more than one lock).

[1022] Under lock state sharing, modifying the value of a lock associated with a resource is achieved by atomically changing the reference to a shared lock state currently associated with that resource with a reference to another shared lock state that holds the new value corresponding to the modified lock value. The acquisition of a lock by a transaction amounts to changing the value of a lock, which, under lock state sharing, as stated above, amounts to changing references to shared lock states. Similarly, locking operations that modify the value of a single lock at a time, such as releasing a single lock, or delegating a single lock, are implemented under lock state sharing by changing references to shared lock states.

[1023] Lock state sharing has been employed in persistent object systems and programming languages, in which the granularity of locking is the object, and where

transactions commonly manipulate very large numbers of objects (in the order of 10^5 objects, or more) as a result of the relatively small size of objects (typically, between 20 and 40 bytes). This combination results in transactions requesting a large number of locks, making the space consumed to represent a single lock an important performance parameter.

[1024] **FIG. 1** illustrates such a lock state sharing approach. In particular, **FIG. 1** depicts a simple situation where only two lock values, represented by two shared lock states **110** and **111**, are in use by the system. The locks on resources **O1** and **O2** are represented as pointers to the same shared lock state since they have the same value, whereas the lock on **O3**, which has a different value, is a pointer to a different shared lock state.

[1025] **FIG. 1** also depicts acquisition, by a transaction **T3**, of a read lock on resource **O2** in accordance with lock request **101**. Given an initial set of shared lock states, e.g., as represented by a table thereof in accordance with initial set **102A**, a resultant set of shared lock states is computed, e.g., as represented by a table thereof in accordance with resultant set **102B**. In the illustrated configuration, the requester (or functionality responsive to the lock request) builds the new lock value that the lock on resource **O2** should have (see building sequence **103**). As illustrated, the initial set **102A** (i.e., the then current set) of shared lock states is searched (lookup **105**) for a shared lock state that represents the lock value **104**. If none is found, the new lock value is recorded in the table as a shared lock state whose pointer is then used to encode the new value of the lock on resource **O2**. Alternatively, if a matching shared lock state is found, its pointer is used to encode the new value of the lock on resource **O2**. To effect the change in lock value, the shared lock state pointer encoding the value of **O2**'s lock is atomically replaced with the one just obtained. If the atomic update fails (e.g., because of a concurrent lock management operation), then the sequence of operations may be performed again.

[1026] Various lock state sharing implementations have been devised and may be employed in a given realization. Straightforward implementations typically keep track of the locks of each transaction by recording in one or more book-keeping data structures

the references to all resources locked by each transaction. An improved variation, eliminates such book-keeping of locked resources, and instead allows shared lock state to be mutated to reflect the result of releasing all the locks of a transaction at once (i.e., a bulk lock release, which is the most common form of lock release operation). Although more complex, such an implementation can reduce memory consumption by eliminating lock book-keeping data structures and makes bulk lock release independent of the number of locked resources. Addition of memoization and inlined ownership test techniques can also considerably improved the performance of locking operations.

[1027] While a variety of lock state sharing techniques and implementations may be employed (*see generally*, L. Daynes, *Implementation of Automated Fine-Granularity Locking in a Persistent Programming Language*, Software-Practice and Experience, 30(4):325-361, 2000, for a review of some exemplary variations; *see also* U.S. Patent 6,182,186 to Daynes, which is incorporated herein in its entirety by reference, and which describes in detail some suitable implementations of lock state sharing techniques), the description that follows focuses on an implementation that employs memoization techniques (see below) and does not keep track of acquired locks. Performance, both in terms of processing time and memory consumption, of the illustrated implementation has generally been preferable as compared with other implementations. Nonetheless, based on the description herein, persons of ordinary skill in the art will appreciate implementations that build on any of a variety of techniques for lock state sharing. Adaptation (for other such variants of lock state sharing) of the mechanisms presented in detail herein is straightforward.

Ignore-conflict relationships

[1028] Ignore-conflict relationships allow customization of the conflict detection mechanisms of a lock manager. A traditional lock manager diagnoses a conflict based on a lock mode compatibility table. Each lock mode corresponds to one or more particular data operations. A transaction processing system enforces the condition that a transaction performs an operation if and only if it owns the lock on the data manipulated by that operation in a mode that corresponds to that operation. If another transaction already

owns the lock in a mode incompatible with the requested mode, a conflict is diagnosed, and, as a result, some action to handle the conflict is triggered (e.g., insertion of the request to the lock pending queue, or notification of the conflict to some conflict resolution entity). In general, lock manager facilities and suitable implementations thereof are well known to persons of ordinary skill in the art.

[1029] By using ignore-conflict relationships between transactions, a transaction manager can override the lock manager decision, which is based otherwise only on lock mode compatibility. Typically, the lock manager associates each transaction T with a set $ICW(T, c)$ per type of conflict c . When the lock manager uses read and write lock modes, c can have three values: rw (read-write conflicts), wr (write-read conflicts), and ww (write-write conflicts). Suitable extensions to systems that provide larger (or different) sets of lock modes are straightforward.

[1030] In general, a conflict can be represented as a pair (c, s) , where c identifies the type of the conflict, and s is the set of owners of the lock that conflicts with the requester. For a given request issued by a transaction T , a lock manager that is cognizant of ignore-conflict relationships can ignore the conflict (c, s) if s is a subset of $ICW(T, c)$. Any of a variety of transaction systems and lock manager implementations that utilize ignore-conflict relationships are possible and will be recognized by persons of ordinary skill in the art. For example, some suitable variations are illustrated in L. Daynes, M.P.

Atkinson, and P. Valduriez, *Customizable Concurrency Control for Persistent Java*, in S. Jajodia and L. Kerschberg, editors, *Advanced Transaction Models and Architectures, Data Management Systems*, chapter 7, Kluwer Academic Publishers, Boston, 1997. In some cases, implementations that utilize ignore conflicts representations can support implementations of other advanced transaction models, such as those that support conditional conflict serializability using parameterized lock modes. See e.g., co-pending U.S. Patent Application No. 09/663,208, entitled Implementation of Parameterized Locking Modes Using Ignore-Conflict Relationships, naming Laurent Daynes and Ole J. Anfindsen as inventors, which is incorporated herein by reference in its entirety.

Lock Delegation with Lock State Sharing

[1031] In some implementations in accordance with the present invention, lock delegation proceeds in two steps: first, the validity of the requested bulk operation is verified; then, the transfer of ownerships between the delegators and delegates is performed atomically with respect to all other locking operations (lock acquisitions, lock releases, and other lock delegations). Both validation and performance of the bulk transfer are described herein. However, as will be clear to persons of ordinary skill in the art having benefit of this disclosure, certain implementations in accordance with the present invention need not implement both validation and performance of the bulk transfer, or need not implement the particular validation or bulk transfer techniques illustrated. Indeed, the techniques employed for validation and performance of the bulk transfer are largely separable and may be employed independently of each other. Indeed, some realizations of a bulk transfer operation may rely upon an independent facility to ensure the validity of a bulk delegation request.

[1032] Accordingly, although exemplary implementations described herein include both aspects in a unified design, persons of ordinary skill in the art will recognize, particularly in light of the claims that follow, the potential independence of validation of a requested bulk delegation operation and performance of such an operation (with or without validation). In view of the foregoing, and without limitation, bulk transfer techniques are first described, followed by description of a suitable, though separable, validation technique. To facilitate understanding, an illustrative set of lock manager data structures are introduced first. Then, ownership transfer is discussed next for the following cases: (1) single lock delegation, (2) memoization-based delegation, (3) optimized bulk lock delegation, and (4) lock delegation when the delegated lock has a non-empty queue of pending requests.

Lock Manager Data Structure

[1033] On exemplary lock manager that implements lock state sharing includes four principal data structures:

1. *Lock State*. A data structure that represents the value of a lock (a lock value for short).
2. *Locking context*. Information maintained by the lock manager for each transaction (or equivalent).
3. *Thread Locking context*. Information maintained by the lock manager for each thread of control involved in lock management functions.
4. *Table of shared lock states (TSLs)*. An associative search data structure that keeps track of all the shared lock states currently used to represent locks. Lock state values are used as key for searches.

[1034] Conceptually, the value of a lock is represented as sets of transactions (typically, one set per lock mode) representing the owners of the lock, and a queue, which may be empty, of pending lock requests. One efficient data structure representation for each transaction set is as bitmaps (or bit-sets). However, other ways of representing sets of transaction identifiers are also suitable. For example, representations of a lock as a linked-list of lock request control blocks can also be used. In such case, a single linked-list representing the union of all the transaction sets may be used.

[1035] For simplicity, the description that follows assumes an abstract representation that includes a set of transactions per lock mode (denoted *Owners(l, M)*) for a given lock *l* and a mode *M*, and a queue of pending lock request *Q(l)* for lock *l*. Furthermore, only read and write lock modes are considered. Variations for a larger set of lock modes are straightforward and, based on the description herein, will be readily appreciated by persons of ordinary skill in the art.

[1036] As a general matter, the implementation described herein does not assume a particular technique for associating a resource with the lock that protects it. For a given resource *r*, its lock is denoted *lock(r)*. Note that in the context of a lock state sharing implementation, *lock(r)* is typically implemented as a pointer to a shared lock state. In some implementations of lock state sharing, *lock(r)* is associated with *r* by storing lock state directly in storage of resource *r*. Suitable techniques for efficiently maintaining

such a direct association despite the possible movements of a locked resource across various level of a memory hierarchy (e.g., main-memory and secondary storage) are detailed in one or more of the above-identified and/or incorporated references.

Single Lock Delegation

[1037] Using lock state sharing techniques, delegation of a single lock follows the same principle as other locking operations such as described above with reference to **FIG. 1**. For example, a lock state data structure is first initialized with the value that the lock should have after delegation, and used as a key for searching the TSLS. If no shared lock states with that value is found, a new one is recorded in the TSLS. The lock pointer to the shared lock state representing the lock being delegated is then atomically replaced with the pointer to the new lock value obtained from the TSLS. If the atomic replacement fails, the whole procedure is repeated, but using the most recent shared lock state associated with the resource whose lock is delegated.

[1038] The lock value representing the effect of delegation is computed by replacing the delegators with the delegates from each of the owners sets involved with the delegation. In one variant of lock state sharing considered herein, granting a lock in mode M also grants the lock in all other modes covered by M . Lock coverage is denoted using the arithmetical comparators (e.g., $=$, $<$, $>$, \leq , \geq). When considering read and write lock modes only, the following coverage of lock modes is defined: $W > R$, $W = W$ and $R = R$. Given these definitions, computing the value of a lock after a delegation can be implemented according to the following pseudocode:

```

LockState computeEffectOfDelegation(delegators, delegates,  $M$ ,  $o$ )
begin
    // copy the original lock state representing the delegated lock's current value
    LockState  $l \leftarrow lock(o)$ 
    // modify its owner set to reflect the effect of delegation
    foreach  $M_i, M_i \leq M$ 
         $Owners(l, M_i) \leftarrow (Owners(l, M_i) - delegators) \cup delegates$ 
    end
    return  $l$ 
end

```

where o is the resource whose lock is delegated.

[1039] A similar computation can be performed for a more general case that does not rely on the semantics described above (i.e., that a lock granted in mode M automatically grants the lock in mode covered by M). This more general case slightly changes the pseudocode as follows:

```

LockState computeEffectOfDelegation(delegators, delegates, o)
begin
    LockState  $l \leftarrow lock(o)$ 
    for all  $M_i$ ,
        if ( ( $Owners(l, M_i) \cap delegates == \emptyset$ )
             $Owners(l, M_i) \leftarrow (Owners(l, M_i) - delegates) \cup delegates$ 
        endif
    end
    return  $l$ 
end

```

[1040] Variations on the basic implementation are also suitable. For example, in some implementations, changes in the owner sets of a lock value may involve further state changes. For instance, in a bitmap-based implementation, each lock value may be associated with a type that indicates whether the lock is owned by a single owner, whether it is owned in read-mode only, or whether it has a non-empty queue of pending requests. In such a representation, changing the owner sets of the initial lock value may also require changing its type.

[1041] Also, a lock manager may maintain direct pointers to frequently used shared lock states, and omit such states from the TSLs. For instance, shared lock states representing locks owned in read, or write, mode by a single owner (SO lock states) may be omitted from the TSLs. Instead, the lock manager may maintain in the locking context of each active transaction direct pointers to its corresponding SO lock states. Thus, each locking operation resulting in a SO lock state is saved a TSLs search. This method is directly applicable to lock delegation. For instance, if delegating a lock results in a SO lock state, then the TSLs does not need to be searched. Instead, the resource's pointer to the lock state representing its lock is atomically replaced with the pointer to the

SO lock state found in the locking context of the delegatee. These and other efficiency improvements may be included in a given implementation.

Memoization-based Delegation

[1042] Memoization is a technique that can be successfully used to speeding up locking operations in implementations that employ lock state sharing. The principle of memoization is adapted to lock management as follows. Each thread acting on behalf of a transaction is supplemented with a small memoization cache. In a simple form, the cache has one entry per locking operation. Each cache entry includes a pair of pointers to shared lock states, denoted i (initial) and f (final). The values of these shared lock states are related by the relation $f = op(T, i)$, where T is the transaction owning the memoization cache, and op is the locking operation associated with the memoization cache entry made of i and f . Transaction T is an implicit key to the cache since each cache is associated to only one transaction.

[1043] For a given locking operation op operating on an object o , the memoization cache is used as follows: if $lock(o) = i$, then $lock(o)$ is atomically replaced with f ; otherwise, the lock manager is invoked to compute $op(T, lock(o))$, $lock(o)$ is atomically replaced with $op(T, lock(o))$, and the memoization cache is updated with the pair $lock(o), op(T, lock(o))$.

[1044] In a SPARC V9 implementation, probing the memoization cache and subsequently exchanging the current lock pointer with the probe's result upon a cache hit takes 6 instructions. To this, one must add any additional instructions for setting up the memoization sequence, which includes instructions for whatever calling convention is used if memoization sequences are not inlined, plus instructions for setting registers to the addresses of both the memoization cache and the location of the resource's pointer to the shared lock state representing that resource's lock. Overall, an inlined memoized locking operation rarely takes more than 10 SPARC instructions.

[1045] SPARC architecture based processors are available from Sun Microsystems, Inc, Palo Alto, California. SPARC trademarks are used under license and are trademarks

or registered trademarks of SPARC International, Inc. in the United States and other countries. Products bearing SPARC trademarks are based upon an architecture developed by Sun Microsystems.

[1046] To adapt this mechanism to lock delegation, a more complex key is employed to lookup cache entries associated to lock delegation operations. The new key uniquely identifies the triple made of the delegators, the delegates, and the initial lock value (represented by a lock pointer). This substantially increases the number of instructions to use a memoization cache. A solution to circumvent this problem is to allocate a memoization cache for each multiple-lock delegation requests, that is, requests for delegating the locks of several resources. Such requests specify a set of resource whose lock must be delegated. They are processed by iterating over the delegated resources (explicitly identified in the lock delegation operation), and delegating their locks one by one. In this case, the delegators and delegates remains fixed across the multiple single lock delegation operations that are performed. Hence, a cache entry need only include a pair of pointers to shared lock state. The delegators and delegates are implicit. The memoization cache can be allocated for the duration of the multiple-lock delegation operations (typically, as an automatic variable on the thread's stack), and memoization can be performed as indicated above. The use of memoization for such requests may be parameterized according to some threshold on the number of delegated locks.

[1047] Memoized lock delegation saves a complex full-blown lock delegation operation. In particular, it saves the costs of testing the validity of a lock delegation since a cache hit means that a similar delegation has already been validated. However, a single-lock delegation operation pays the complexity of computing a key based on the delegators, delegates and initial lock state. Accordingly, in some implementations, it may be desirable to limit use of memoization techniques to multiple-lock delegation operations.

Bulk Lock Delegation

[1048] A lock delegation is said to happen in bulk when the lock manager is requested to delegate at once all the relevant locks of some transactions to one or several other transactions. As described above, a bulk lock delegation operation may, in general, allow some selection of those locks to be delegated, for example, in some implementations it may be desirable to delegate only locks owned (or held) in a particular mode (e.g., read locks, write locks), locks protecting new objects only, etc. Nonetheless, for simplicity, the description that follows focuses on an exemplary case of bulk delegations that delegate all the locks of the delegator transaction(s). Accordingly, as used herein, "all locks" will be understood to be all the relevant locks given some particular implementation.

[1049] In the context of lock state sharing, bulk delegation offers computational efficiency when the number of locks of the delegators is larger than the total number of lock values representing current locks, which is usually the case. In this case, neither the lock manager nor its clients need to explicitly keep track of locked resources. Instead, the lock manager can find the locks of the delegators by scanning the TSLS, and modify their value atomically with respect to other operations.

[1050] Modifying a shared lock state of the TSLS has two consequences. First, the position of the shared lock state in the TSLS should be changed according to its new value, since this value is used as a key for associative search. Second, the modification of the shared lock state may have turned it into a duplicate of an existing shared lock state of the TSLS. That is, the new value may already exist in the TSLS. Having such duplicates is not incorrect, but it is sub-optimal in terms of memory consumption. Duplicates that may be subject to further updates as a result of some subsequent bulk operations (e.g., bulk lock release, or bulk delegation) should be tracked in order to apply the corresponding updates to them as well. Such tracking is necessary since some duplicates may still be used to represent the value of the lock of some resources. Duplicates can be eliminated once no resource uses them to represent the value of their lock. In some realizations, a lock manager may eagerly reclaim duplicates

asynchronously with the help of a resource manager by atomically exchanging all pointers to a duplicate with pointers to its original.

[1051] As explained above, some of the locks of the delegators may also be represented by duplicates. Hence, bulk delegation should also modify these duplicates to reflect the effect of lock delegation. Note that once modified, a duplicate remains a duplicate, but of another lock state. This is because the original that was duplicated has also gone through the same modification. Lastly, as already mentioned, some frequently used shared lock states may be omitted from the TSLS in some realizations. Typically, the shared lock states that represent single-owner lock value may be omitted. Modifying such single-owner lock values for delegation may also change them into duplicates of another shared lock state. Alternate storage for certain lock states (e.g., single-owner lock values) is omitted in some of the description that follows.

[1052] **FIGS. 2 and 3** illustrate how bulk delegation proceeds in an exemplary implementation. In particular, **FIG. 2** depicts an exemplary functional sequence. In response to a bulk delegation request, which may be validated (201) in some implementations, shared lock state values in an encoding of a set of shared lock states (e.g., the TSLS and any ancillary data structures) are checked to determine whether one of the owner sets for the lock value includes a delegator transaction. If so, each delegator transaction is deleted (203) from the owner set(s) of the shared lock state where it appears and each delegatee transaction is added (204) thereto. **FIG. 3** more formally depicts an exemplary functional sequence for performing a bulk delegation of locks. More particularly, operation 301 implements for each relevant locking mode, the removal of delegators and addition of delegates. Additional operations manage and process duplicates.

Validity of Lock Delegation

[1053] Some realizations implement validation of bulk delegation requests. For example, as illustrated in **FIG. 2**, validation 201 may be performed prior to performance of the bulk delegation. One illustrative implementation of a validation method is

illustrated in **FIG. 5** and includes initial use of computationally-efficient, though conservative, tests **501** followed, if necessary, by a general method which (in comparison) is computationally-expensive. The description that follows focuses first on the general method. Use of additional tests as optimizations will then be better understood in the context of the general method.

[1054] The general method includes iterating (**502**) over an encoding of the set of shared lock states, and for each shared lock state of the encoding having at least one associated owner set that includes at least one of the delegator transactions, applying a validation test. In general, a delegation is valid if and only if the new value of the lock can also be achieved by some sequence of lock acquisitions. In other words, delegation is valid if and only if it is possible to verifying that none of the delegates conflict with the remaining current owners of the lock (i.e., those that do not delegate the lock). Accordingly, delegating a lock owned in read mode only is always valid. Similarly, delegating a lock with a single owner to a single delegatee is always valid, irrespective of the mode in which the lock is owned.

[1055] A request for delegating a lock to multiple transactions may be invalid when the delegates cannot ignore-conflict between each other. For instance, delegation of a write lock from one transaction to two other transactions is invalid if the two transactions cannot ignore write-write conflicts between each other.

[1056] A request for delegating a lock may also be invalid when the lock is owned in incompatible modes by multiple transactions. Locks with multi-mode ownerships result from using ignore-conflict relationships between transactions. The same relationships may not hold between the remaining owner of the lock and some or all of the delegates. In such case, the request is invalid. For instance, let us assume two transactions T_1 and T_2 such that T_1 can ignore read-write conflicts with T_2 and, symmetrically, T_2 can ignore write-read conflicts with T_1 . Let l be a lock such that $Owners(l, Read) = \{T_1\}$ and $Owners(l, Write) = \{T_2\}$. Delegation of l by T_1 to another transaction T is valid only if T can also ignore read-write conflicts with T_2 and symmetrically, T_2 can ignore write-read conflicts with T .

[1057] In general, the validity of a bulk lock delegation should be determined before performing any actual lock delegation, otherwise, many locks may have been delegated before realizing that the request is invalid. A straightforward method for verifying the validity of a bulk delegation is to scan the TSLS a first time and apply the validation test for every shared lock state representing the value of a lock that is going to be delegated. Note that duplicates of shared lock states do not need to be scanned to determine the validity of a request.

[1058] **FIG. 4** formally illustrates a functional sequence that implements such a general validation test for delegation of a single lock. Such a functional sequence may be employed as general validation test **503** and as employed for lock-value by lock-value validation (**601**) in the formal illustration of **FIG. 6** (described below). The general validation test can benefit from various implementation dependent lock state information. For instance, in some implementation, a lock value carries a type of information that indicates whether the lock is owned by a single transaction only. In this case, delegating a lock owned by one transaction only to another transaction is always valid, and validation is not needed.

[1059] This costly additional scan may be avoided in common situations by using two simple conservative tests presented below. The two conservative tests are illustrated in **FIG. 5** and more formally specified in **FIG. 6**. The first conservative test, test **602**, builds on the concept of a set of transactions that belong to the owner set of at least one read-write shared lock state. A conservative estimate of this *wset* can be efficiently maintained for comparison against the set of delegators. The use of such a *wset* will be understood as follows.

[1060] If all the delegated locks are owned in read mode only, the request is intrinsically valid since there cannot be any conflicts. This compatibility can be quickly determined if the TSLS keeps track of all the transactions that belong to one or more owner sets of at least one read-write shared lock state recorded in the TSLS. This set, denoted *wset*, is only a conservative indication of the set

$$\bigcup_{\forall l \in \text{TSLs}, \text{Owners}(l, \text{Write}) \neq \emptyset} (\text{Owners}(l, \text{Read}) \cup \text{Owners}(l, \text{Write}))$$

[1061] It is conservative in the sense that it is a superset of the set of transactions involved in at least one read-write shared lock states. Trying to precisely maintain *wset* can be computationally expensive. Instead, a fairly precise conservative estimation of *wset* can be maintained as follows:

- Whenever a shared lock state *l* such that *Owners* (*l*, *Write*) $\neq \emptyset$ is recorded in the TSLs, (*Owners* (*l*, *Read*) \cup *Owners* (*l*, *Write*)) is added to *wset*.
- Whenever the TSLs is scanned for a bulk lock operation (e.g., delegation or release), *wset* is recomputed.

[1062] Recomputing *wset* upon every scan of the TSLs is inexpensive (especially if owner sets are implemented as bitmaps) and makes *wset* accurate again. Inaccuracy results from executing non-bulk lock delegation or lock release operations, but is tolerable because any such inaccuracy simply overstates the contents the *wset*. Note that if the transaction processing system does not have recourse to single lock delegation and single lock release operations, then *wset* will always accurate.

[1063] In the validation technique illustrated in FIG. 6, a second conservative test, test 603, is employed if test 602 fails to assure the validity of the requested bulk delegation. The second conservative test, test 603, begins by determining if a requested bulk lock delegation is valid by comparing the ignore-conflict relationships of the delegators and the delegates. If a transaction delegates all its lock to another transaction, then, the delegation is guaranteed to be valid if, for each type of conflicts, the set of transactions that the delegatee can ignore conflicts with is a super-set of each of the sets of transactions that each of the delegators can ignore conflicts with. This test can be generalized to multiple delegators and delegates as follows:

$$\forall t_d \in \text{delegates}, \forall t_s \in \text{delegators}, \forall C \in \{rw, wr, ww\}, \\ (ICW(t_s, C) - (\text{delegators} \cup \{t_d\})) \subseteq ICW(t_d, C)$$

[1064] This initial test is then combined with a second test verifying that all the delegates can ignore conflict with each other if at least one of the delegated locks is owned in write mode by at least one of the delegators. If both component tests of conservative test **603** are satisfied, then validity of the requested bulk delegation is assured.

[1065] Pseudocode of **FIG. 6** formally illustrates one particular realization of test **603**; however, more generally, test **603** may be understood as follows.

(1) If there are no delegatee transactions such that, for each type of conflict, the corresponding set of transactions with which the delegatee can ignore conflicts is not a super-set of the set of transactions that includes those transactions with which delegator transactions can ignore conflict of this type, excluding the delegator transactions themselves, and

(2) if there is at least one shared lock state representing a write lock owned by at least one of the delegator transactions and there are no delegatee transaction such that the delegatee transaction cannot ignore conflict with all the other delegatee transactions,

then, validity of the requested bulk delegation is assured.

[1066] In general, for the second part of test **603** to work efficiently, a second set can keep track of those transactions for which there is at least one shared lock state of the encoding of the set of shared lock states that represents the value of a lock owned in write mode by those transactions. Note that this second set is a subset of the set used for the conservative test **602** and can be maintained in almost the same way except for the transactions that are added to the set upon an update of the set, i.e., only the write owners of shared lock states are added to the set, instead of the union of the read and write owners.

[1067] Although tests **602** and **603** are efficient and cover most common cases, the two tests presented above are conservative, and therefore, their failure does not

necessarily indicate that a delegation is invalid. In such case, to precisely determine validity, the implementation of **FIG. 6** finds the value of the locks currently owned by the delegators, employing the general validation test procedure illustrated above with reference to **FIG. 4**.

[1068] It will be understood that the general method can be used alone, or with one or both of the conservative tests. In general, potential combinations include following:

1. Apply the general method,
2. if conservative test **602** is false, apply the general method.
3. if conservative test **602** is false, apply conservative test **603**; if conservative test **603** is false, apply the general method.

[1069] For clarity of illustration, the realization formally described using pseudocode in **FIG. 6** only takes into account the locks of the delegators represented by shared locks states recorded in the TSLS. Based on the description herein, persons of ordinary skill in the art will appreciate the desirability of representing certain lock states outside a TSLS encoding. Accordingly, in an implementation that does not record some lock state in the TSLS, additional verification is needed. For instance, if frequently used lock states, such as SO lock states, are maintained outside of the TSLS, the validity test needs to take them into account. Additions to traverse additional data encodings of some locks states are straightforward.

[1070] In practice, it is a good idea to split the TSLS into two tables: one for read only shared lock states, and one for read-write shared lock states. This reduces the costs related to validation, such as scanning the TSLS for read-write lock states, or re-evaluating the *wset*, since only scans of the read-write TSLS sub-table would be subject to these additional costs.

Impact on Queue Management

[1071] Lock delegation may change the status of a pending lock request. The most straightforward case is when a lock with a non-empty pending queue is delegated to one

of the transactions waiting for the lock. A less trivial example, occurs when a lock is delegated to a transaction with ignore-conflict relationships with another transaction waiting for the delegated lock. For instance, let us assume three transactions T_1 , T_2 and T_3 such that T_3 can ignore read-write conflict with T_2 , and T_3 is currently waiting for a read lock request for an object o locked in write mode by T_1 only (i.e., $Owners(lock(o), Write) = \{T_1\}$ and $Owner(lock(o), Read) = \emptyset$ and $Q(lock(l)) = \{T_3\}$). If T_1 delegates its lock to T_2 , then T_3 can be granted the lock immediately as well. Hence, upon a lock delegation, the lock manager re-evaluates the queue of pending request.

Illustrative Variations

[1072] While the invention has been described with reference to various embodiments, it will be understood that these embodiments are illustrative and that the scope of the invention is not limited to them. Many variations, modifications, additions, and improvements are possible. In addition, to those described above, two major sources of variation include (1) use of the bulk delegation of locking capabilities that are associated with entities or objects (e.g., transactions cooperating groups, logical databases, etc.) that control visibility or access to shared data or resources, and (2) differing and/or more complex sets of locking modes.

[1073] One illustrative set of locking modes includes browse (B), read (R), intention to read (IR), upgrade (U), write (W), intention to write (IW) and read with intention to write (RIW). Of these, R, B and IR can be classified as modes having read semantics (M_r) and W, U, IW, and RIW can be classified as modes having write semantics. Although a variety of conditional compatibility configurations are possible, in one exemplary configuration, the following modes may be considered conditionally compatible:

M_r	M_w
R	W
R	U
R	IW
R	RIW
IR	U
IR	W

[1074] Other commonly employed lock modes include intention none (IN), share or shared (S), intent share (IS), update (U), exclusive (X), intent exclusive (IX) and share with intent exclusive (SIX), which generally correspond to the previously introduced browse, read, intention to read, upgrade, write, intention to write and read with intention to write lock modes. In general, the set of lock modes employed is implementation dependent and any suitable set may be employed. Based on the detailed description herein of bulk delegation and validation techniques in the context of read and write lock modes, persons of ordinary skill in the art will appreciate suitable variations for alternative sets of lock modes.

[1075] More generally, realizations in accordance with the present invention have been described in the context of particular embodiments. These embodiments are meant to be illustrative and not limiting. Accordingly, plural instances may be provided for components described herein as a single instance. Boundaries between various components, operations and data stores are somewhat arbitrary, and particular operations are illustrated in the context of specific illustrative configurations. Other allocations of functionality are envisioned and may fall within the scope of claims that follow. Finally, structures and functionality presented as discrete components in the exemplary configurations may be implemented as a combined structure or component. These and other variations, modifications, additions, and improvements may fall within the scope of the invention as defined in the claims that follow.
